IMPORTANT - TECHNICAL VALIDATION STATUS

The **GDCR v5.0 - "Maverick Ghost Edition"** framework presented in this document was developed, tested, and validated exclusively within **Sandbox** and **SAP BTP Trial** environments over the last 15 days. The reported metric results—including the **90% reduction in sprawl** (API-Proxy, Packages, and Technical Users)—refer to controlled **Proof of Concept (PoC)** scenarios and do not represent implementation in a real or stable production environment.

This document is intended as an **emergent architectural guide**, not as a prescriptive production blueprint. Any corporate adoption **must be preceded by formal risk assessment, security evaluation, governance review, and operational validation**, in accordance with each organization’s internal standards.

Disclaimer: This article reflects the author’s personal architectural perspective and does not represent an official SAP position or recommendation.

Abstract (Revised — Version 5.0, Final)

Large-scale enterprise API ecosystems tend to evolve into complex landscapes as integration volumes grow. A recurring structural issue is **proxy sprawl** at the API gateway layer, driven by 1:1 technical mappings. This pattern is mirrored at the orchestration layer, where artifacts are organized by system rather than by business semantics. This leads to persistent package sprawl.. Over time, these choices amplify credential proliferation and architectural entropy.

This paper introduces **Gateway Domain-Centric Routing (GDCR)**, a vendor-agnostic framework that routes API traffic based on **business domain and process semantics**. GDCR repositions API management as **background technical infrastructure**, exposing a stable interface aligned with the CORE business model. Routing decisions are externalized into a **semantic control plane**, enabling deterministic routing through standardized naming conventions.

The reference implementation, validated **in SAP BTP Integration Suite** sandbox and trial environments, realizes GDCR through two complementary execution patterns: **the Domain-Centric Routing Pattern (DCRP) at the API management layer and the Package Domain-Centric Pattern (PDCP)** at the orchestration layer**.**

- **90% reduction in API proxies (41 → 4)**,
- **90% reduction in orchestration packages (39 → 4)**,
- **69% reduction in technical users (39 → 12)**,
- **95% reduction in deployment time**.

Across more than 106,000 routed calls, DCRP (APIM) / PDCP (CPI) maintained near-perfect success rates (99.92–100%) with routing overhead consistently in the **1–4 ms** range. GDCR standardizes **business semantics rather than tools**, allowing vendor technologies to remain interchangeable execution details.

1. Executive Summary — Business Intent vs. Technical Background

The core philosophy of GDCR v5.0 is the semantic alignment of the integration layer with the core business. By decoupling business intent from technical infrastructure, the API gateway and the orchestration layer no longer act as exposed technical artifacts; instead, they operate as domain translators, mapping business semantics to vendor-specific execution paths.

Key principles:

- Semantic unification: APIs and orchestrators must reflect the business domain language, fully abstracting underlying technologies, protocols, and platforms.
- Technical background isolation: Vendor-specific implementations (BAPIs, adapters, legacy protocols, proprietary engines) remain strictly in the background, invisible to API consumers.
- Standardized business governance: While each vendor employs different technical mechanisms, business semantics, naming conventions, routing logic, and domain structure remain unique, stable, and business-oriented across the entire integration landscape.

The complexity of GDCR is internal and algorithmic; for the business and the developer, it results in a simplified, flat, and human-readable surface.

2. Vendor Implementation Matrix (Conceptual)

GDCR is a universal, vendor-agnostic concept. Each platform utilizes its native policy or extension mechanisms to execute metadata-driven domain routing.

Vendor	Technology path	Implementation role
SAP BTP	JavaScript + KVM	PROVEN: Dynamic routing,action normalization, and domain-centric consolidation.
Google Apigee	JavaScript + KVM	THEORETICAL: Uses native Key-Value Maps for metadata-driven target resolution.
Azure APIM	C# policy expressions	THEORETICAL: Policies intercept URIs and query Table Storage or Cosmos DB.
AWS API Gateway	Lambda + DynamoDB	THEORETICAL: Lambda function acts as an intelligent, metadata-driven router.
Kong	Lua plugin + Redis/Postgres	THEORETICAL: Lua plugins perform real-time routing decisions based on metadata.
MuleSoft	DataWeave 2.0 + Object Store	THEORETICAL: DataWeave acts as the primary decision engine backed by Object Store.

Important scope clarification:

- DCRP **does not apply** to **SAP standard APIs**
- PDCP **does not apply** to **SAP standard, pre-packaged integration content – SAP CPI**
- The framework is intended **exclusively for custom-built APIs and custom integration packages**, whether exposed through API Management or implemented in orchestration platforms

Standard SAP-delivered APIs and pre-built integration packages follow their own lifecycle, governance, and semantic models and are **explicitly out of scope** for this work.

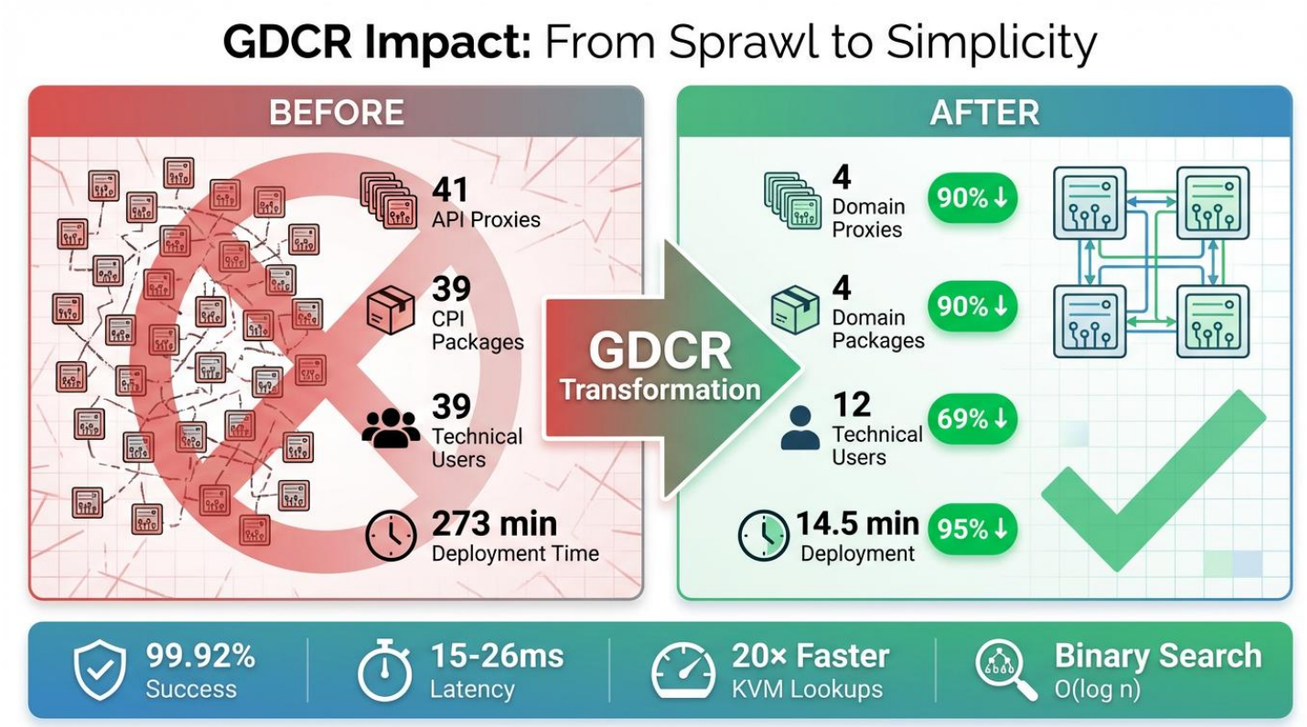

Figure 1 - Consolidated view of the transformation from 41 API proxies, 39 CPI packages, 39 technical users and 273 minutes of deployment time to 4 DCRP domain proxies.PDCP 4 domain packages, 12 but used only 4, one per domain, technical users and 14.5 minutes of deployment, with 99.92% success, 15–26 ms routing latency, 20× faster KVM lookups and binary-search O(log n) scalability.

Intermediate Conclusions: Vendor-Agnostic Applicability of GDCR

Gateway Domain-Centric Routing (GDCR) demonstrates that **semantic, domain-centric routing** can effectively decouple business intent from technical infrastructure in large-scale enterprise API ecosystems. By externalizing routing decisions into a **metadata-driven control plane** and aligning integration design with business domains and processes, GDCR reduces architectural coupling, mitigates long-term governance risks associated with proxy and orchestration sprawl, and establishes a foundation for **AI-ready routing semantics**.

Although empirically validated within the **SAP BTP Integration Suite**, the architectural principles underlying GDCR are **vendor-agnostic by design** and align with capabilities commonly available in modern API management and integration platforms. As such, the framework is theoretically applicable to other gateway and orchestration technologies that support metadata-driven routing, policy enforcement, and centralized control planes.

Overall, the results indicate that **domain-centric, metadata-driven architectures** represent a viable foundation for **next-generation API governance**, enabling scalable evolution, reduced vendor lock-in, and improved resilience across heterogeneous enterprise integration landscapes.

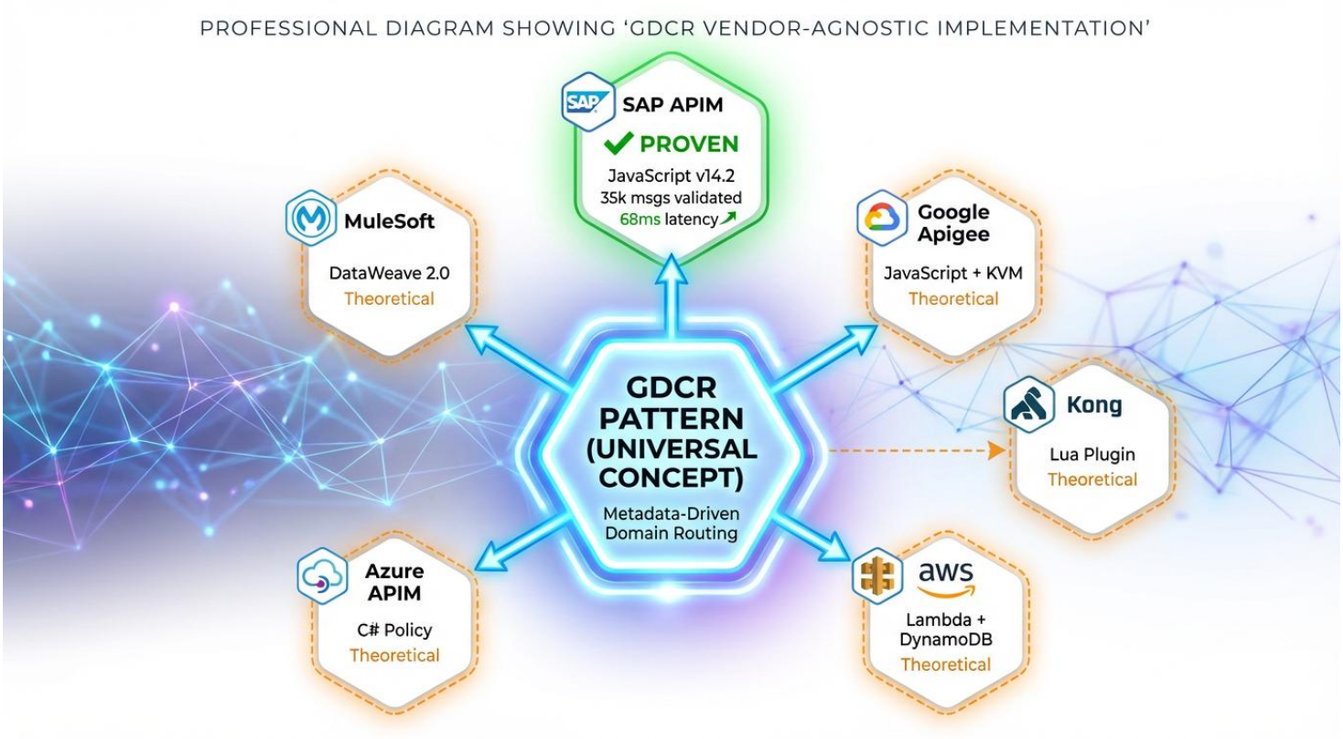

Figure 2 - GDCR as a Vendor-Agnostic Pattern for Metadata-Driven Domain Routing.

Conceptual overview of GDCR as a universal, metadata-driven routing model:

Empirically proven in SAP API Management and theoretically implementable in other gateways such as MuleSoft (Data Weave 2.0), Google Apigee (JavaScript + KVM), Kong (Lua plugin), Azure API Management (C# policies) and AWS API Gateway with Lambda and DynamoDB.

1. Introduction

1.1 The API and Orchestration Sprawl Crisis

Modern enterprises operate hundreds to thousands of APIs across heterogeneous backend systems and integration platforms. Over time, conventional design practices tend to produce a triple sprawl effect: proxy sprawl at the API gateway layer, package sprawl at the orchestration layer, and credential sprawl across both.

At the API gateway layer, the prevailing 1:1 mapping between external APIs and backend services results in dozens or hundreds of narrowly scoped proxies, each duplicating security policies, rate limits, and monitoring logic. In parallel, orchestration artifacts—such as packages, iFlows, recipes, or processes—are frequently organized by vendor or application (e.g., *Salesforce Orders*, *QuickBooks Invoices*, *Workday Employees*) rather than by business domain. This vendor-centric organization fragments monitoring and transformation logic, complicates lifecycle management, and forces teams to reason about the integration landscape using technical system names instead of business capabilities.

As new projects, vendors, and regions are introduced, each typically requires new proxies, new orchestration artifacts, new credentials, and new naming conventions. Over time, API gateways, integration platforms, and identity stores evolve independently, with limited central coordination. The resulting sprawl increases operational cost, slows change, and introduces blind spots in governance and security posture—particularly in environments spanning multiple cloud providers and API gateway technologies.

Guided Impact Simulation (Methodological Note)

The impact metrics presented in this section (and illustrated in Figures 1,2,3,4) are derived from a **guided simulation** designed to provide architectural orientation. These figures do not represent static production data from a single client but rather a modelled scenario based on common enterprise integration debt. The purpose of this simulation is:

- **Pedagogical Illustration:** To visualize the magnitude of operational waste generated by 1:1 technical mapping model.
- **Strategic Direction:** To serve as a compass for decision-makers to identify efficiency bottlenecks.
- **Scalability Benchmarking:** To demonstrate how technical complexity translates into financial debt and delivery inertia, guiding the transition toward semantic abstraction.

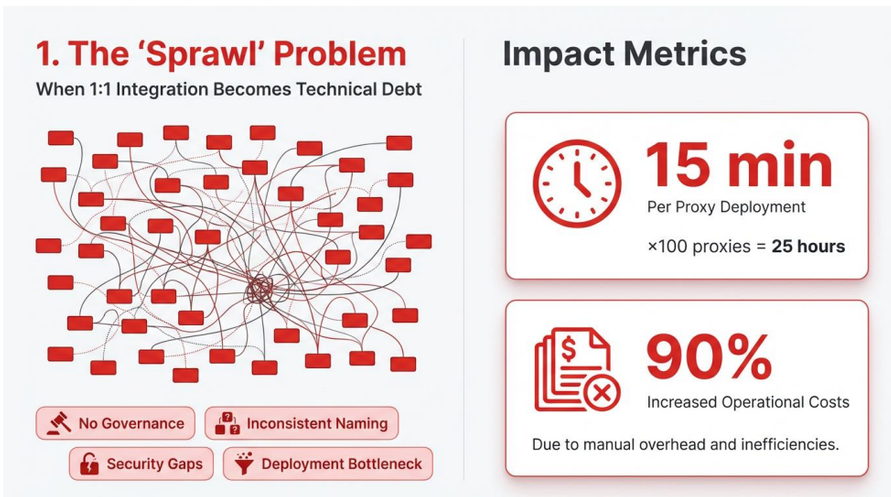

Figure 1 – The Challenge: Proxy Sprawl across API gateway, orchestration and backend layers in a typical enterprise integration landscape.

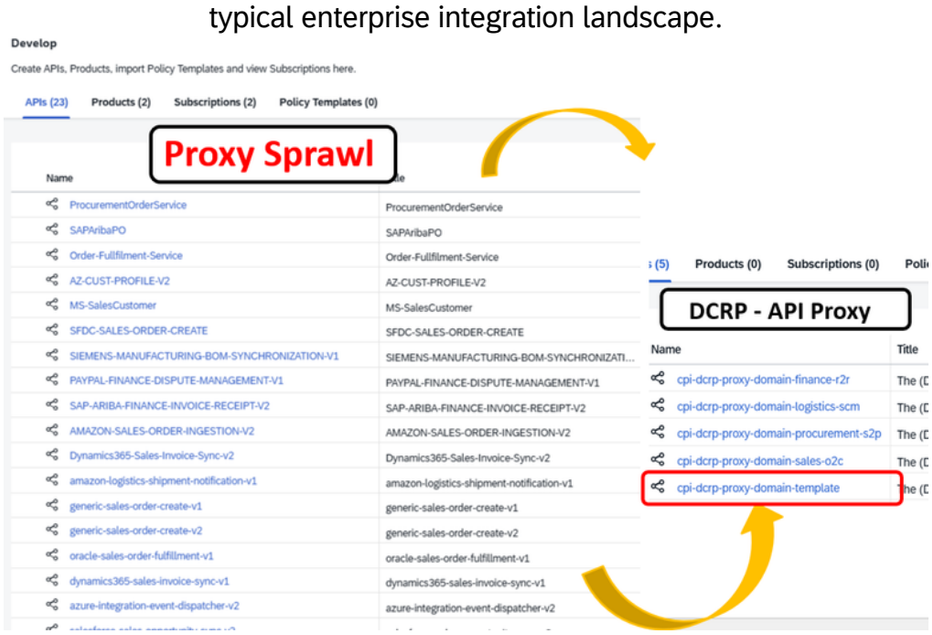

Figure 2: Sample Illustrative from SAP BTP Integration Suite – API Management

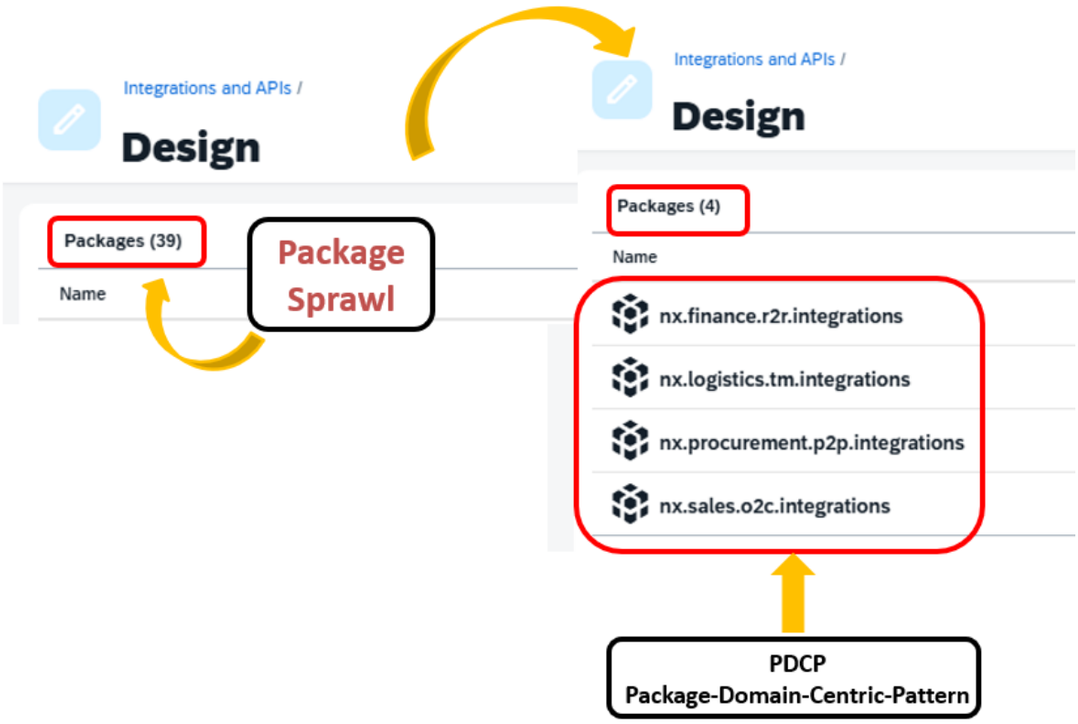

Figure 3: Sample Illustrative from SAP BTP Integration Suite – CPI – 39 Packages vs 4 packages

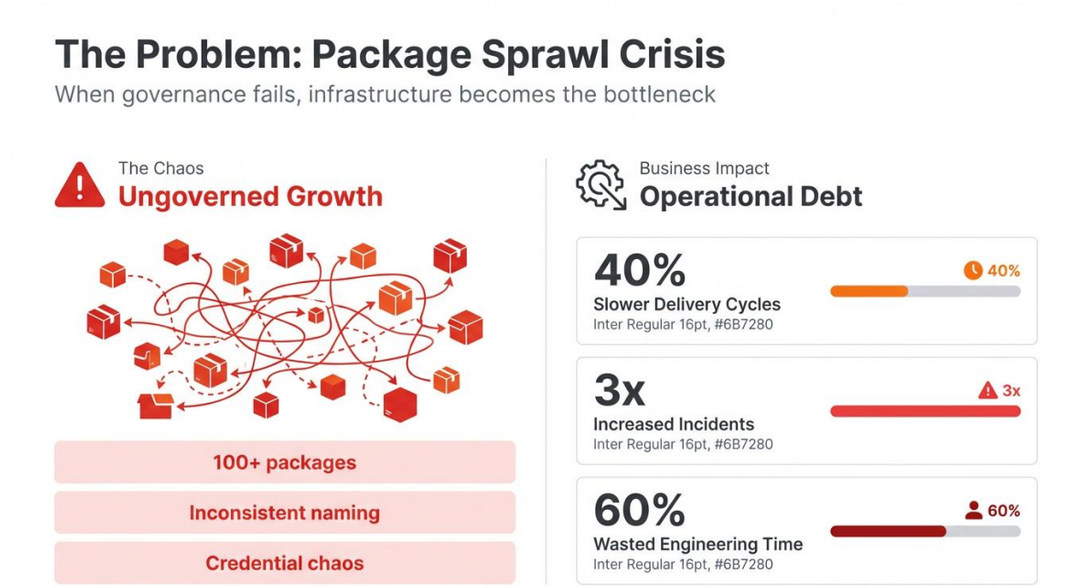

Figure 4 – Package/Orchestration Sprawl: vendor-centric organization of integration artifacts leading to fragmented governance and duplicated logic.

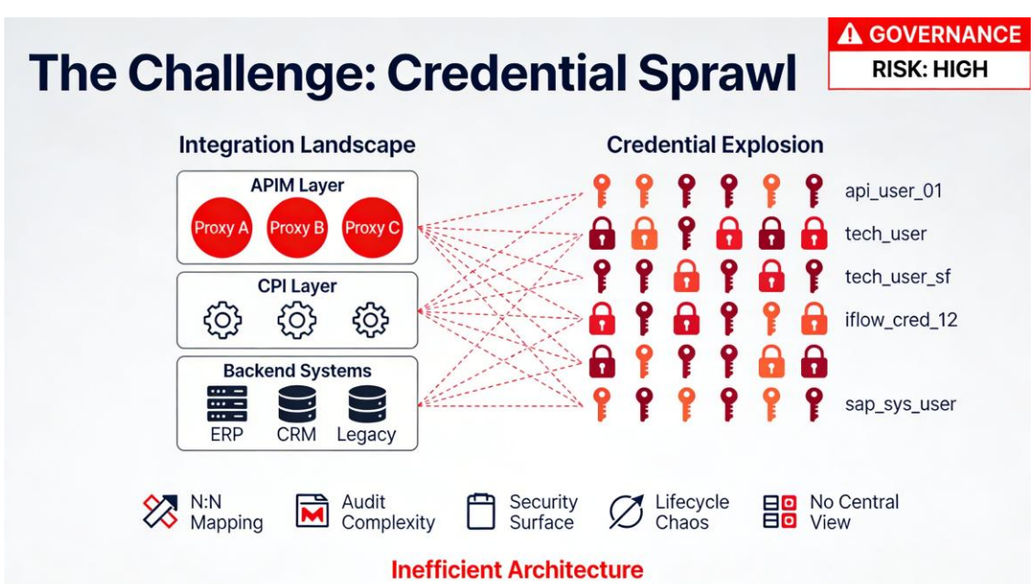

Figure 6 – The Challenge: Credential Sprawl across API gateway, integration and backend layers, showing N:N credential mappings and complex lifecycle management.

1.2 The Technical–Business Impedance Mismatch

In most organizations, business stakeholders think and plan in terms of domains—Sales, Finance, Logistics, HR—while technical teams configure gateways and integrations using vendor and system identifiers such as Salesforce, SAP, QuickBooks or Workday. This gap creates a persistent technical–business impedance mismatch: URLs, proxy names, package structures and user accounts all encode technical decisions, not business semantics.

Traditional API gateway patterns expose these implementation details directly to consumers, for example via URLs like /api/v1/salesforce-prod-endpoint-347/customers. Such designs leak vendor names and environment information, couple client applications to backend choices, and make migrations or consolidations (for example, Salesforce → another CRM) operationally expensive. The same misalignment appears in orchestration platforms, where the primary unit of organization is "system of origin" instead of "domain of value", making it difficult to reason about end-to-end business processes or enforce consistent naming and security conventions.

This impedance mismatch has direct architectural consequences: routing rules must be duplicated per system, cross-cutting concerns are replicated across proxies and packages, and governance teams have no single place where "Sales Order-to-Cash" or "Finance Record-to-Report" are visible as first-class, cross-platform concepts.

1.3 Research Contribution

Gateway Domain-Centric Routing (GDCR) addresses these challenges by treating business domains and processes as the primary abstraction for routing, packaging, and governance, rather than vendors or technical endpoints. GDCR elevates the API gateway and orchestration layers into a semantic control plane, where requests are routed by domain, entity, and action (e.g., /sales/orders/create) and subsequently resolved to concrete backend systems through metadata.

The main contributions of this work are:

• A vendor-agnostic architectural model (GDCR) in which API gateways route requests based on business domain semantics, with routing logic externalized into key–value metadata stores rather than hardcoded proxy configurations.

• Two concrete execution patterns for SAP BTP Integration Suite that instantiate this model:

– The Domain-Centric Routing Pattern (DCRP), which consolidates multiple system-specific proxies into a small number of domain-aligned hubs at the API management layer.

– The Package Domain-Centric Pattern (PDCP), which reorganizes orchestration artifacts into domain-aligned CPI packages and iFlows.

• A mathematically optimized reference implementation (JavaScript engine v15.1 “Maverick Ghost”) combining cached metadata lookups, O(1) action normalization, and O(log n) KVM search, empirically validated with more than 33,000 routed calls at 99.92–100% success rates and low single-digit millisecond routing overhead.

• Conceptual evidence that the same semantic routing model can be implemented on other gateway and orchestration platforms (e.g., Apigee, Kong, AWS API Gateway, Azure API Management, MuleSoft) using their native policy languages, indicating that GDCR is portable beyond SAP-centric landscapes.

An additional industrial-grade variant of the engine (v15.2 “Maverick Phantom”) achieves 1–4 ms routing overhead under extended stress tests; however, this variant is considered out of scope for the reference implementation and is referenced only to illustrate that the GDCR model itself does not impose a practical performance ceiling.

2. Background and Related Work

2.1 API Sprawl and Governance

Current literature defines API sprawl as the uncontrolled proliferation of endpoints and gateways, often driven by time-to-market pressures. Traditional mitigations (catalogs, linters, and CI/CD gates) act as "band-aids" but fail to address the root cause: the hard-coded 1:1 coupling between external APIs and backend systems. This rigidity prevents business agility and creates significant technical debt.

2.2 Domain-Driven Design (DDD) in Integration

While DDD is a standard in microservices, it is rarely applied at the gateway or orchestration layers. Most integration landscapes remain "system-oriented" (e.g., "Salesforce iFlow"), leaking implementation details. GDCR explicitly applies DDD to the integration layer, treating the technology as a background detail while exposing a stable domain-centric foreground (e.g., /sales/orders). This ensures the integration fabric is anchored in the CORE Business.

2.3 Metadata-Driven Control Planes

Modern architectures such as Software-Defined Networking (SDN) and Service Mesh platforms rely on control planes to decouple routing decisions from physical infrastructure. These control planes typically optimize technical attributes such as latency, protocols, topology, or region.

GDCR adapts this control-plane concept to enterprise integration by elevating **business identifiers**—domain, entity, and action—as the primary routing surface. By externalizing routing logic into metadata keyed by business semantics, the API gateway becomes an AI-ready platform in which integration artifacts are indexed by meaning rather than by technical implementation details.

2.4 Positioning of GDCR

GDCR does not claim to reinvent dynamic routing; it adapts proven Control-Plane/Data-Plane principles from Software-Defined Networking (SDN) specifically to resolve the chronic 'sprawl' and 'technical-business mismatch' found in legacy SAP integration landscapes.

GDCR positions itself as a **structural governance approach** rather than a documentation- or catalog-driven solution. While catalogs and discovery tools improve visibility over existing sprawl, they typically operate on top of a fragmented topology that already reflects historical design debt.

In contrast, GDCR reduces sprawl structurally by enforcing semantic routing templates and domain-centric contracts at the integration layer. API gateways and orchestration platforms cease to be collections of system-specific artifacts and instead operate as **domain translators**, where vendor-specific paths, adapters, and protocols remain background implementation details.

This positioning allows consumers to interact with a single, stable business contract, while backend vendors remain interchangeable execution choices. As a result, governance, monitoring, and evolution can be managed at the semantic level of the core business rather than at the level of individual systems or technologies.

2.4 The Technical Foundation of GDCR

2.4.1 Metadata as Control Plane (Key-Value Maps)

In the reference implementation, routing decisions are externalized into a metadata layer using Key-Value Maps (KVM). The KVM serves as the persistent memory of the GDCR control plane, storing the mappings between semantic routing keys (domain, entity, action) and concrete execution targets. This approach decouples routing behaviour from the gateway code, ensuring that backend changes do not require proxy redeployment.

2.4.2 Policy-Based Execution (JavaScript Routing Engine)

A single, lightweight JavaScript policy acts as the universal execution engine for GDCR. For every incoming request, the engine parses the semantic URL, normalizes the action, and resolves the target endpoint via the metadata store. This ensures that the same execution logic is applied across all

domains, providing deterministic behaviour and consistent governance regardless of the backend system.

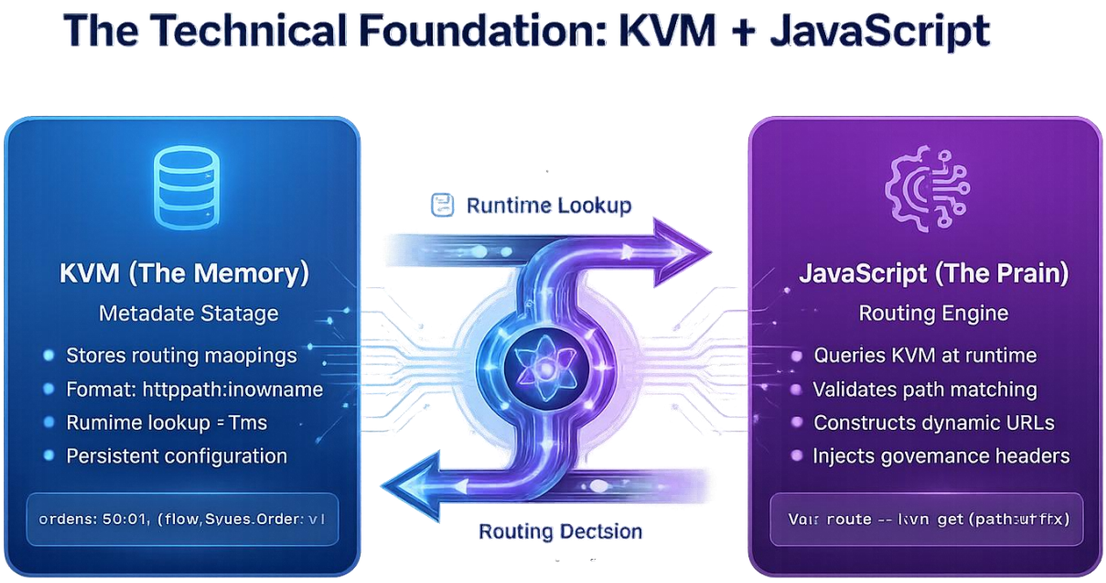

Figure 7 - GDCR Control Plane: Metadata-Driven Routing via KVM and Policy Execution in SAP API Management

2.5 Theoretical Vendor Implementation Matrix

GDCR is a universal architectural concept. While the reference implementation utilizes SAP BTP, the framework is designed to be portable across major API Management platforms by leveraging their native policy engines and metadata storage mechanisms.

2.5.1 Platform-Specific Implementation Paths

Each vendor provides unique technical mechanisms to execute the GDCR routing logic (Parse → Normalize → Lookup → Route):

- **SAP BTP (Proven):** Uses **JavaScript policies** combined with **Key-Value Maps (KVM)**. The logic performs a context.getVariable to extract the path, executes a binary search or direct lookup in the KVM, and sets the target.url dynamically.
- **Google Apigee:** Employs **JavaScript or Java Callout policies** with native **KVMs**. Apigee's high-performance KVM caching is ideal for the GDCR metadata store, allowing sub-millisecond resolution of backend targets.
- **Azure API Management:** Utilizes **C# Policy Expressions**. Using the set-backend-service policy, Azure APIM can intercept the incoming URI and perform an asynchronous lookup against **Azure Table Storage** or **Cosmos DB** to resolve the semantic routing key.
- **AWS API Gateway:** Implements a **Lambda Authorizer** or a **routing Lambda** backed by **DynamoDB**. The Lambda function acts as the "Intelligent Router," querying the DynamoDB table (Metadata Plane) to determine the integration path or the specific ARN to invoke.
- **Kong Gateway:** Leverages **Lua Plugins** combined with **Redis**. A custom Lua plugin intercepts the request at the *access* phase, queries the Redis cache for the domain/entity/action key, and dynamically reassigns the upstream target.
- **MuleSoft Anypoint:** Uses **DataWeave 2.0** and the **Object Store**. DataWeave functions as the primary decision engine, transforming the incoming business request into a technical routing key resolved via the Object Store v2.

2.5.2 The Universal Execution Logic

Regardless of the technology stack, the "Maverick Ghost" core logic remains consistent:

1. **URI Extraction:** The gateway parses the semantic segments: /{domain}/{entity}/{action}.
2. **Canonical Normalization:** The native engine (JS, C#, Lua, or DataWeave) maps the heterogeneous input verb to one of the **15 GDCR canonical action codes** (e.g., onboard → c).
3. **Metadata Query:** The engine performs a lookup in the platform's metadata repository using the synthesized routing key.
4. **Dynamic Binding:** The resolved technical endpoint, protocol adapter, and security context are injected into the request flow, decoupling the consumer from the implementation.

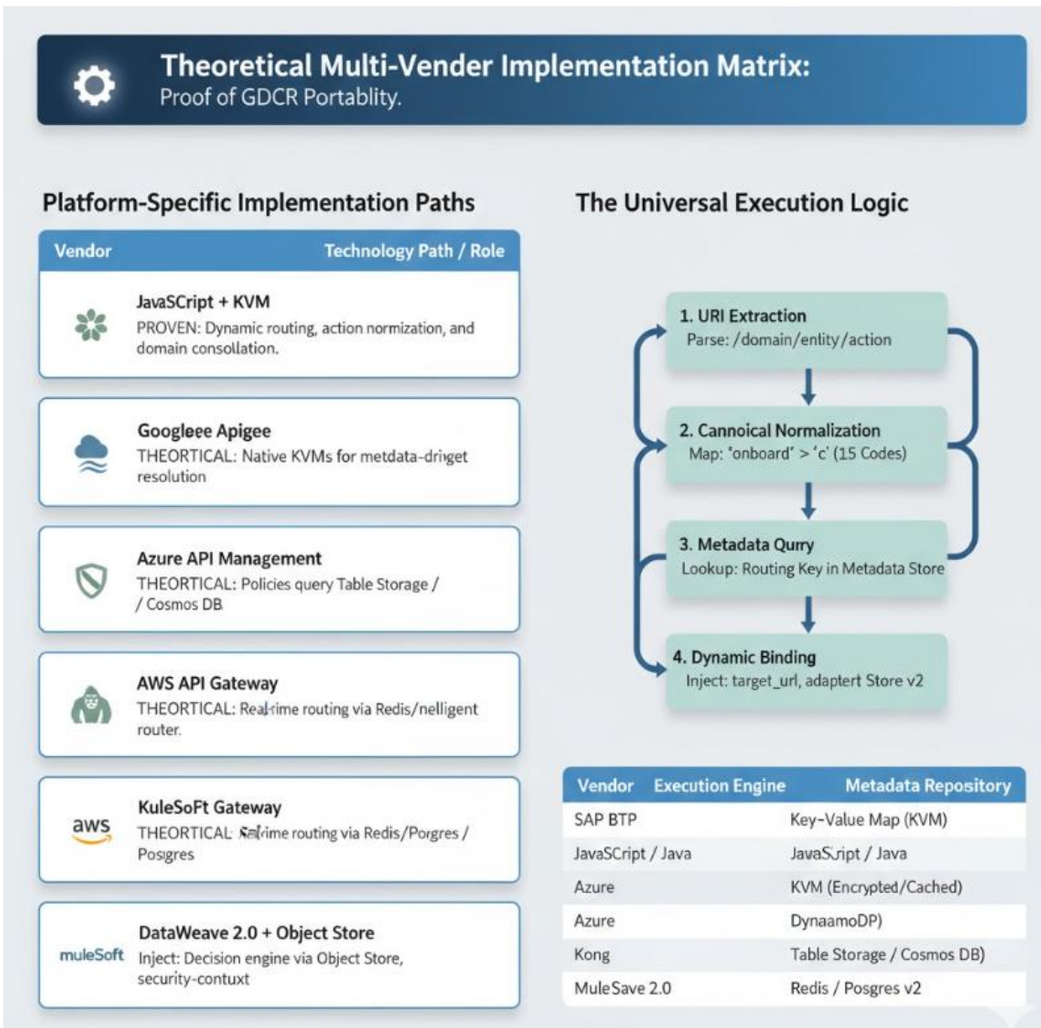

Figure 8 - Theoretical Multi-Vendor Implementation Matrix: Proof of GDCR Portability.

GDCR does not claim novelty in isolated techniques such as metadata-driven routing, DDD, or gateway consolidation. Its contribution lies in unifying these elements into a single, enforceable semantic control plane spanning gateway and orchestration layers.

3.0 Domain-Centric Execution Patterns: DCRP and PDCP

While GDCR defines a semantic routing model independent of specific technologies, its practical realization is achieved through two complementary patterns: DCRP at the Gateway layer and PDCP at the Orchestration layer. Together, they ensure the entire integration landscape is semantically aligned with the CORE Business while technical details remain in the background.

3.1 DCRP — Domain-Centric Routing Pattern (Gateway Layer)

The DCRP is an architectural pattern that consolidates multiple backend services into a single, domain-oriented API proxy.

- Domain-Centric Organization: APIs are grouped by business domain (e.g., Sales, Finance) rather than technical systems (e.g., Salesforce, SAP).

- Metadata-Driven Agility: Leverages the KVM foundation to enable real-time routing updates without proxy redeployment.
- Protocol-Agnostic Interface: Transparently handles REST and SOAP backends behind a stable business contract.

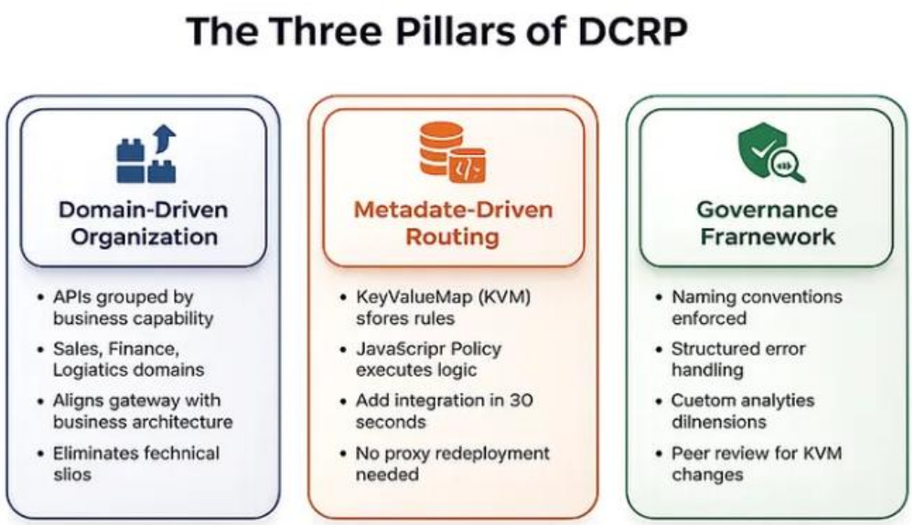

Figure 8 — The three pillars of DCRP

DCRP Decision Framework

- **Use DCRP When:** Domain density is high (10+ APIs in the same domain), integration changes are frequent, centralized governance is required, or rapid deployment is business-critical.
- **DO NOT Use When:** Services have no business logic connection, there are fewer than 10 total APIs, or teams lack governance maturity.

Figure 9 — DCRP Decision Framework: When to Use vs. When NOT to Use

3.2 PDCP — Package Domain-Centric Pattern (Orchestration Layer)

PDCP addresses integration package sprawl by replacing the "Technical Silo" model with a domain-centric structure.

- **Business Domain Consolidation:** All iFlows and artifacts related to a domain are grouped into a single, governed package.
- **Standardized Discovery:** Uses the "iFlow DNA" convention to ensure assets are easily categorized and searchable in platforms like SAP Cloud ALM.

- **Tiered Credential Strategy:** Segregates technical users by business criticality (e.g., Transactional vs. Master Data), reducing credential sprawl by 69% (from 39 to 12 users in the reference model).

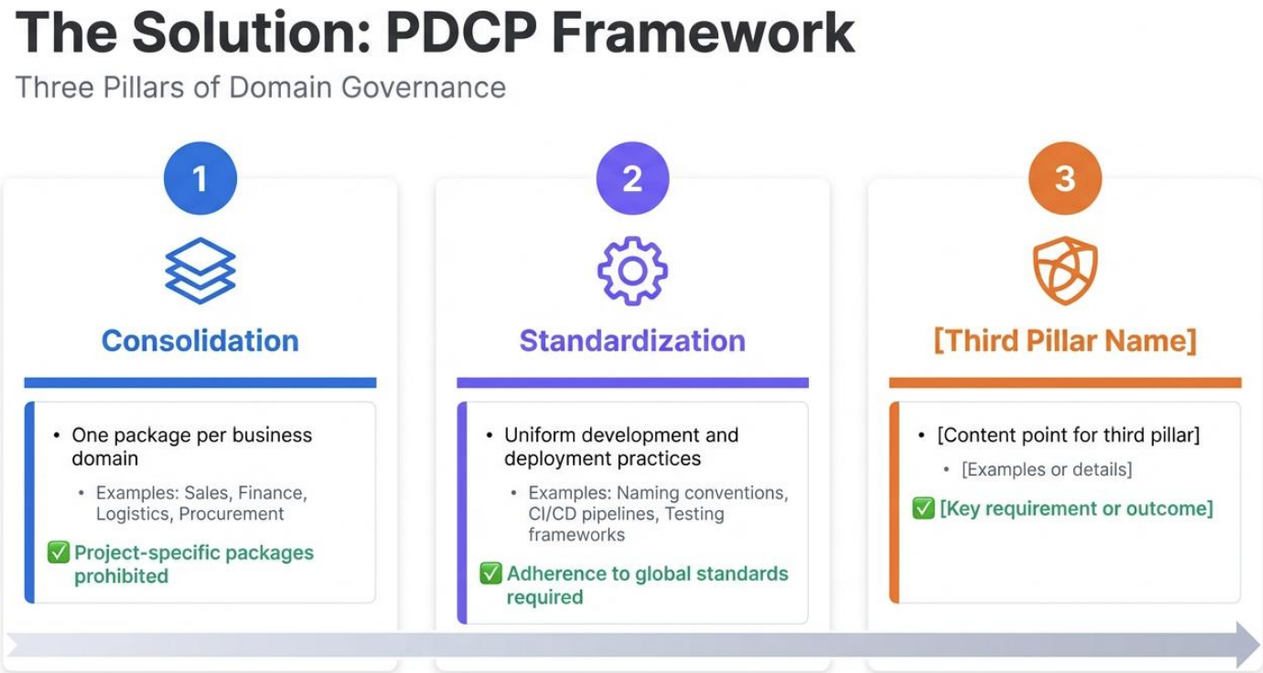

Figure 10 — The PDCP three pillars.

3.3 DCRP and PDCP as a Unified Domain-Centric Model

GDCR achieves its full potential through a **Mirroring Strategy**, where the semantic URL at the gateway (DCRP) is perfectly synchronized with the package structure in the orchestration layer (PDCP). This creates a single semantic thread across all layers, allowing architects to reason about the landscape purely in terms of business value.

This layered realization sets the foundation for the **Security Model** described in the next section, where this semantic abstraction directly reduces the attack surface through **URL Fakery** and **Fail-Fast** enforcement.

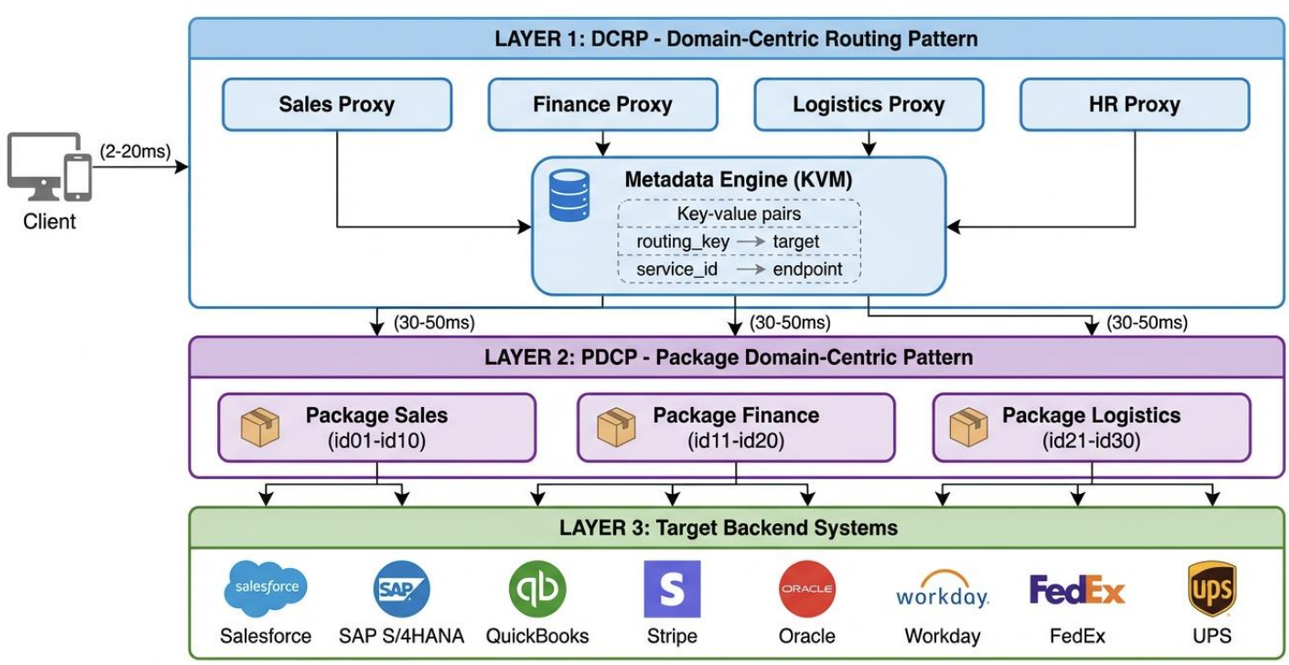

Figure 11 - DCRP and PDCP as a Unified Domain-Centric Integration Model

3.4 Security Model: Semantic URL Fakery and Governance

GDCR implements a security posture known as Semantic URL Fakery. From the consumer's perspective, all requests are directed to clean, business-oriented paths:

- POST https://<apim>/sales/orders/create
- GET https://<apim>//finance/invoices/read
- POST https://<apim>//hr/employees/update

Internally, the gateway resolves these paths using the metadata engine, ensuring no sensitive implementation details leak into the public URL space. This includes the strict masking of:

- Internal Topology: IP addresses or hostnames.
- Vendor Footprints: System codes or vendor names (e.g., ECC, S4H, SFDC, WDAY).
- Environment Exposure: Identifiers such as dev, qa, or region-eu.
- Orchestration Logic: Specific integration package or iFlow names.

While not a replacement for standard AuthN/AuthZ, this "fakery" provides three critical architectural side effects:

1. Attack Surface Simplification: Attackers are presented with a stable, semantically organized URL space. This limits their ability to infer internal technologies or environment structures from URL patterns.
2. Semantic Governance: Governance tools and AI-based analysers can operate directly on the /domain/entity/action space. This allows for the immediate detection of anomalies, such as a "Finance" route inadvertently pointing to a "Sales" backend, without requiring deep inspection of technical IDs.
3. AI-Ready Infrastructure: By indexing all layers (gateway, integration, and backend) with shared business identifiers, the landscape is prepared for AI-assisted routing, conflict detection, and automated mapping. Technical implementation remains an invisible background detail, while business semantics become the primary interface.

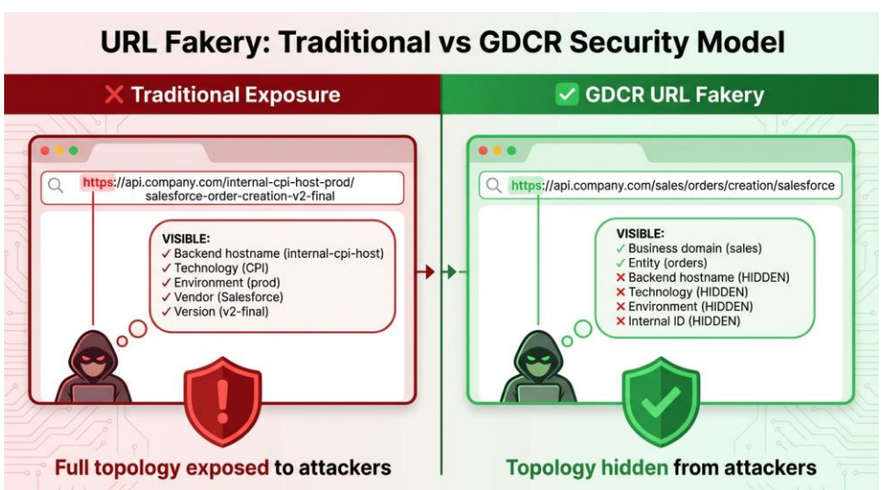

Figure 8 - URL Fakery: Traditional Exposure vs. GDCR Semantic Abstraction.

3.6 GDCR Fail-Fast Security: Performance-Optimized M2M

In the GDCR framework, standard OAuth2 and OIDC are viewed as complementary. However, for high-throughput Machine-to-Machine (M2M) traffic, GDCR introduces a KVM Fail-Fast policy that eliminates the latency of remote token introspection.

Eliminating the OAuth2 Anti-Pattern

Traditional OAuth2 pipelines often trigger remote authorization server lookups for every call—covering signature checks, scopes, and claims. This introduces 150–300 ms of latency and creates multiple external points of failure.

The KVM Fail-Fast Alternative

The GDCR engine performs an in-memory lookup the string httppath in KVM and its associated metadata (/sales/orders/create → kvm string - dcprsalesordersc).

- Ultra-Low Latency: Validation occurs in 1–4 ms.
- Zero External Dependencies: No network calls are required for validation.
- Instant Rejection: If the token is invalid or inactive, the request is aborted immediately, protecting the backend from unnecessary exposure.

This design optimizes high-throughput M2M traffic with near-zero validation latency. While OAuth2 serves user-facing needs, Fail-Fast ensures a high-performance security envelope for semantic routing.

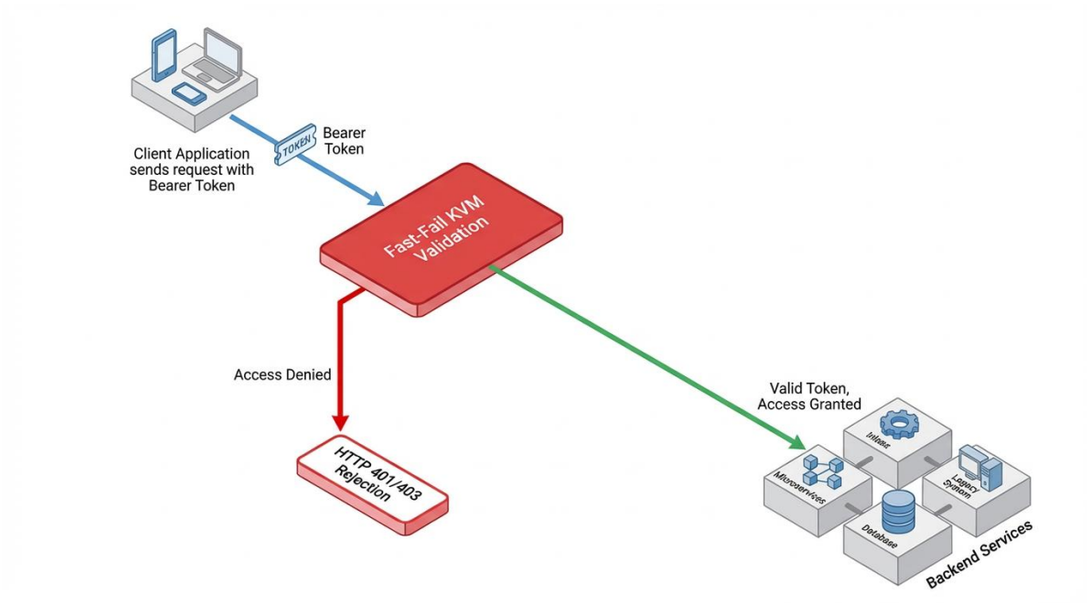

Figure 9 – GDCR Fail-Fast Security Flow.

4. Routing Semantics, Naming, and Package Organization

4.1 Decoupled Logic and Domain-Centric Organization

In GDCR, routing logic is fully decoupled from technical artifacts. Instead of embedding routing decisions in proxies or orchestration flows, the framework maps **semantic identifiers** to execution targets via metadata.

In SAP landscapes, this mapping typically associates:

- CPI package name
- iFlow identifier
- SAP process context

The effective routing decision is derived from the combination of:

- the semantic HTTP path (parsed at the gateway), and
- metadata entries referencing CPI package and iFlow execution units.

This decoupling enables backend changes without redeploying proxies or modifying routing code.

4.2 From Technical Sprawl to Domain Hubs

The framework addresses the "Triple Sprawl" by shifting from a vendor-centric to a domain-centric approach.

- **Traditional Approach (Sprawl):** Organizations typically maintain separate packages per vendor or project (e.g., Salesforce_Orders, Shopify_Orders), leading to fragmented security, redundant mappings, and poor discoverability.
- **PDCP Approach (Domain-Centric):** Integration assets are consolidated into a single governed package per business domain using the format [company-prefix].[business-

domain].[subprocess].integrations. This ensures that all related iFlows share domain governance, naming conventions, and a unified technical user strategy.

4.3 Naming Convention Strategy (Governance, Not Syntax)

Naming in GDCR is a **governance contract**, not an implementation detail. It provides immediate architectural context and ensures consistency across gateway and orchestration layers.

4.3.1 Independence vs. DCRP Synergy

- **Standalone PDCP:** Even without an API Gateway, you achieve a massive consolidation of the SAP Cloud Platform Integration packages, footprint and simplified credential management following this blueprint.
- **DCRP Synergy:** When combined with the **Domain-Centric Routing Pattern (Gateway)**, you create a "Perfect Mirror" architecture. The Gateway handles the semantic routing, while the **PDCP** package provides the structured, high-performance execution layer.

4.4 Naming Convention Strategy (Governance as a Contract)

Naming in GDCR is a governance contract rather than a mere implementation detail. It provides immediate architectural context and ensures consistency across the gateway and orchestration layers.

- DCRP Proxy Naming: Proxies follow the pattern [provider]-[pattern]-proxy-domain-[domain]-[subprocess] (e.g., cpi-dcrp-proxy-domain-sales-o2c).
- Consumer vs. Backend: The consumer interacts with a semantic URL (e.g., /sales/orders/inbound), while the backend reality (e.g., https://<cpi>/http/orders/inbound) remains entirely abstracted and hidden.

4.5 Strategic Benefit: Subprocess Segregation

Segregating by subprocess is intentional. It avoids "monolithic domain proxies" and limits blast radius.

4.5.1 The Three Pillars of PDCP

To sustain this pattern, the architecture stands on three pillars:

1. Consolidation: Mandatory grouping of all iFlows by business area (Sales, Finance, Logistics), strictly prohibiting vendor-specific silos.
2. Standardization: Implementation of the iFlow DNA naming convention for instant discovery via SAP Cloud ALM.
3. Governance: A Domain Architect acts as a gatekeeper to ensure every new integration fits the existing domain logic.

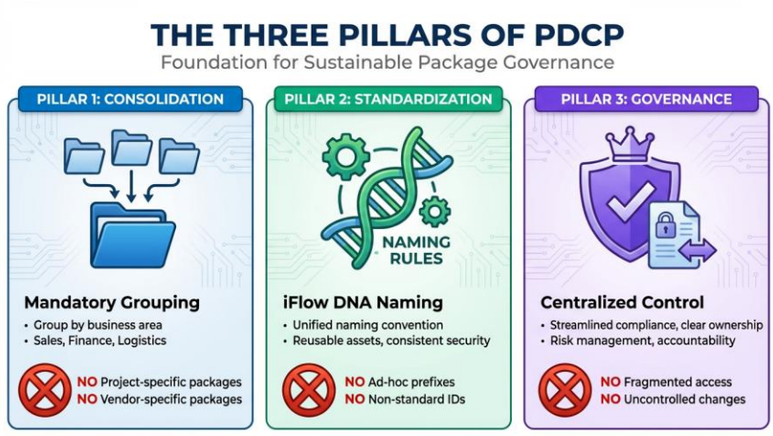

Figure 10 – 3 pillars of PDCP name convention

4.6 The iFlow DNA: Operational Consistency

The Advanced iFlow DNA name allows for deterministic referencing without exposing technical complexity.

- Format: **id[seq].[subdomain].[sender].[entity].[action].[direction].[sync|async].**
- Example: id01.o2c.salesforce.order.s4hana.c.in.sync represents a synchronous inbound order creation from Salesforce to S/4HANA within the Order-to-Cash subprocess.

4.7 Action Normalization: The Semantic Funnel

To keep routing deterministic across different sectors, the GDCR engine normalizes 241 heterogeneous API action verbs into 15 canonical action codes.

- c (CREATE): Includes variants like *add*, *provision*, *register*, or *onboard*.
- r (READ): Covers *fetch*, *query*, *list*, and *search*.
- s (SYNC): Covers *synchronize*, *replicate*, *mirror*, and *refresh*.

Figure 11 – Iflow dna seguency

Examples (Sales – O2C):

- id01.o2c.salesforce.order.s4hana.c.in.sync
- id02.o2c.salesforce.order.s4hana.u.in.sync
- id03.o2c.shopify.customer.s4hana.s.in.sync
- id04.o2c.stripe.payment.s4hana.n.in.sync
- id05.o2c.s4hana.invoice.quickbooks.c.out.sync

4.8 Strategic Benefit: Subprocess Segregation and Security

Segregating by subprocess avoids "monolithic domain proxies" and limits the blast radius of failures.

- **Tiered Credential Strategy:** Each domain package uses tiered technical users segmented by business criticality (e.g., cr.so.o2c for core transactions vs. cr.so.md for master data).
- **Efficiency:** This approach reduces the total number of technical users by **69%** (from approximately 39 to 12 in a standard 4-domain implementation), significantly improving resilience and audit precision.

4.9 URL Structure

To make the semantic model visible and predictable to consumers, GDCR defines a universal URL pattern for all domains and sectors:

- Base patterns:
    - /{domain}/{entity}/{action}

    - /{domain}/{entity}/{action}/{variant}
    - /{domain}/{entity}/{id}/{action}
- Cross-sector examples:
    - GET /sales/customers/read → Read all customers in the Sales domain.
    - POST /sales/orders/create → Create a new sales order.
    - PUT /finance/invoices/123/approve → Approve invoice 123 in the Finance domain.

4.10 Action Normalization

Real-world APIs expose heterogeneous verbs for similar operations (create, provision, register, post Invoice, activate Employee, and so on). To keep routing deterministic and comparable across sectors, the GDCR engine normalizes 241 action variants into 15 canonical action codes.

Conceptually:

- c (CREATE) – includes variants such as create, add, insert, new, provision, register, onboard, postInvoice (when it semantically creates a document).
- r (READ) – covers read, get, fetch, retrieve, query, list, search.
- u (UPDATE) – covers update, modify, edit, change, patch, upsert (when primarily update-oriented).
- d (DELETE) – covers delete, remove, cancel, terminate, deactivate, void.
- s (SYNC) – covers sync, synchronize, replicate, mirror, refresh.

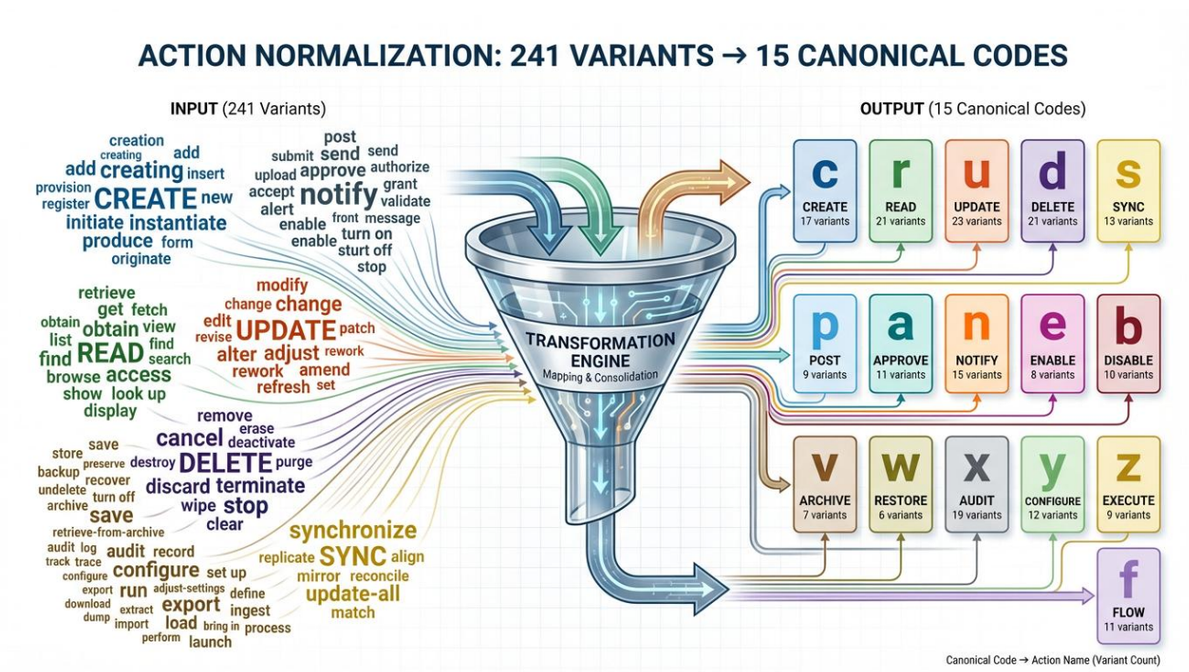

Figure 12 - Infographic showing an action-normalization funnel where 241 heterogeneous API action verbs (such as create, read, update, delete, sync, notify, configure)

5.0 - GDCR in Practice: End-to-End Domain-Centric Integration

This section builds upon the semantic model defined in Section 3 and focuses exclusively on execution and governance aspects.

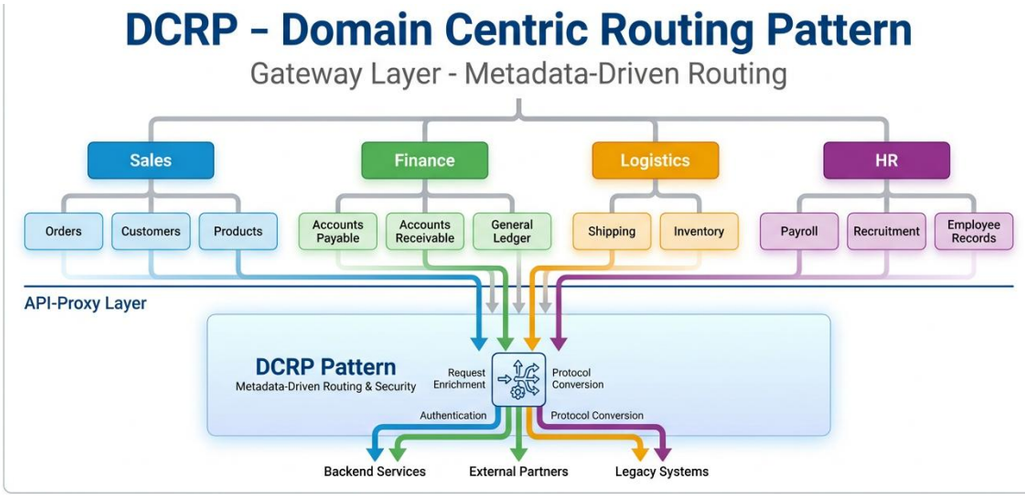

Figure 12 - GDCR, applicable in SAP landscapes as DCRP.

5.1 Designing the GDCR Control Plane (Metadata Layer)

The GDCR Control Plane is defined by a unified metadata metamodel that acts as the **System of Record** for all integrations. In this model, the **semantic contract is first-class**, while the technical endpoint is treated as an ephemeral implementation detail that can change without impacting consumers.

The Metadata Metamodel:

To describe every route regardless of technology, the schema includes:

- **Business Semantics:** domain, entity, action_code, variant.
- **Technical Routing:** adapter, backend_system.
- **Governance & Risk:** criticality, data_classification, owner_team.

Unified Control Plane Matrix (Sample)

Domain	Entity	Action	Variant	Backend System	Criticality	Data Class
sales	orders	c	salesforce	Salesforce CRM	High	Internal
sales	orders	c	sap4hana	SAP S/4HANA	High	Restricted
finance	invoices	a	sap	SAP ECC	Critical	Confidential
hr	employees	r	workday	Workday	Medium	PII
logistics	shipments	c	wms	Custom WMS	High	Internal

Key Principle: No system or iFlow may enter the landscape without a corresponding row in the control-plane metadata.

5.2 Implementing the Routing Engine at the Gateway

The GDCR Routing Engine is a generic, policy-based component. The same execution logic runs for every domain; only the metadata entries differ, ensuring a consistent rollout cadence.

End-to-End Request Flow:

1. Extraction: Client calls /domain/entity/action[/variant].
2. Parsing: Gateway policy parses the URL segments.
3. Normalization: The engine normalizes 241 variants into 15 canonical action codes.
4. Lookup: A routing_key is built to perform a lookup in the metadata store.

5. Resolution: The target_endpoint and adapter are resolved and injected into the flow.

JavaScript

```
// Generic GDCR Routing Engine Core

var path = context.getVariable("proxy.pathsuffix");

var segments = path.split("/").filter(Boolean); // [domain, entity, action]

var actionCode = normalizeAction(segments[2]); // Convert variants to codes (c, r, u, d)

var routingKey = segments[0] + ":" + segments[1] + ":" + actionCode;

// Retrieve metadata from KVM

var targetMapping = context.getVariable("kvm.route." + routingKey);

if (targetMapping) {

    context.setVariable("target.url", targetMapping.url);

    context.setVariable("request.header.X-Adapter", targetMapping.adapter);

} else {

    context.setVariable("gdcr.error", "Route Not Found");

}
```

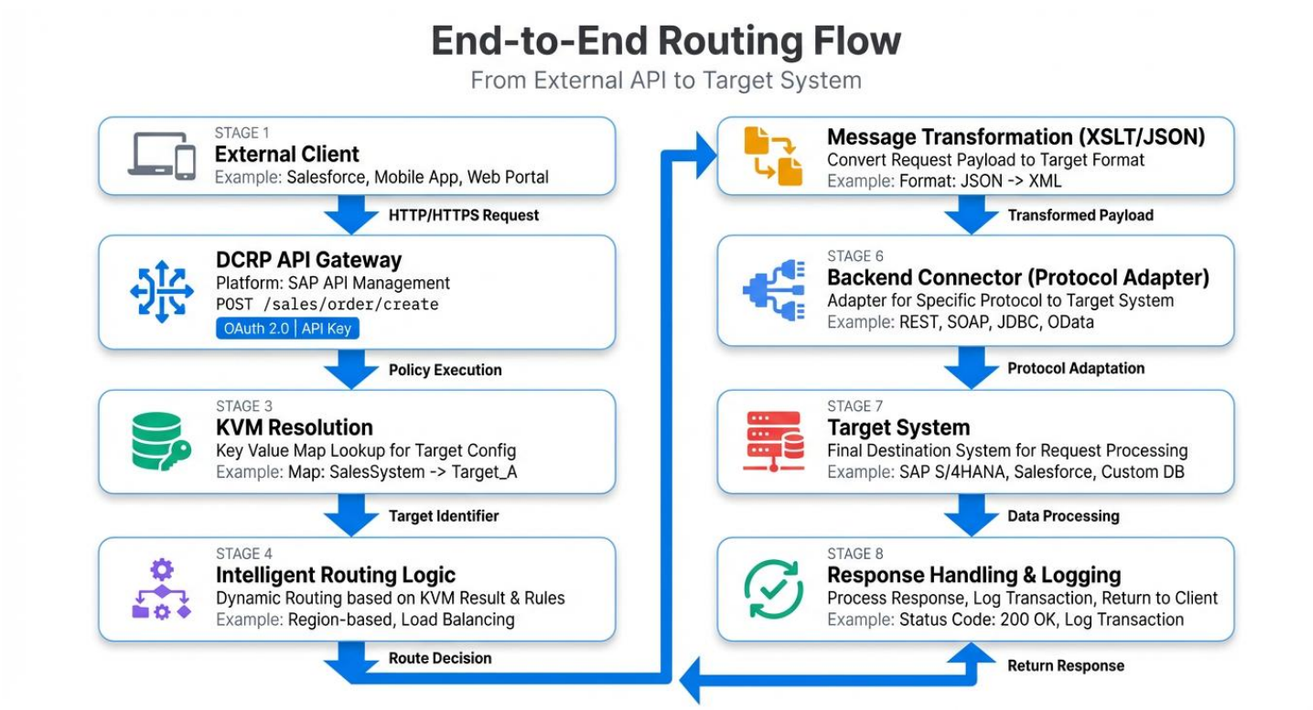

Figure 13 - End-to-End GDCR Routing Flow.Step-by-step.

5.3 Aligning Integration Packages with Domain Semantics

To achieve a "Perfect Mirror" architecture, the PDCP/DCRP patterns ensure that the integration layer uses the same domain vocabulary as the gateway.

The Mirroring Strategy: CPI packages and iFlows are prefixed to match domain semantics (e.g., SO. for Sales, FI. for Finance).

- Sales: /sales/orders/create routes to id01.o2c.salesforce.order.s4hana.c.in.sync
- Finance: /finance/invoices/approve id04.o2c.finance.invoices.s4hana.a.in.sync

Positive Side Effects: Ownership and monitoring naturally reorganize around business domains, making roles like "Sales Integration Owner" obvious and reducing team friction.

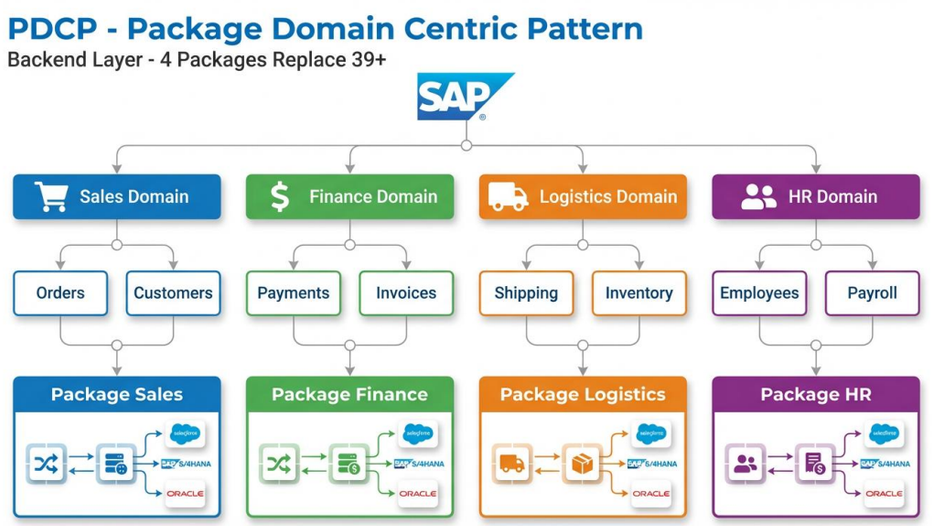

Figure 14 - GDCR, applicable in SAP landscapes as PDCP.

5.4 AI-Ready Security and Governance

GDCR leverages URL Fakery to apply security and observability policies by domain and action, rather than by individual technical proxies.

The Sender-Domain Authorization Matrix: Authorization is decoupled from infrastructure. A matrix defines exactly which semantic operations (e.g., finance/invoices/approve) a sender can invoke, regardless of which backend system currently serves that route.

5.5 Security and Governance Flows over GDCR

GDCR extends the semantic URL fakery model into security, rate limiting, and observability. Because every route is expressed as a stable semantic pattern (/domain/entity/action), security policies are defined once at the domain level and reused consistently across all backend vendors that implement the same business capability.

Authorization is governed through a sender × domain/entity/action matrix. For each sender (application, partner, or channel), the matrix explicitly defines which semantic operations are permitted, independent of the backend system currently serving the route. This decouples authorization from infrastructure changes and simplifies impact analysis when systems are replaced or consolidated.

Because all routes are indexed by business semantics, GDCR enables AI-ready governance. Future governance engines may analyse the semantic control plane to identify redundant routes, detect conflicting mappings across vendors, recommend consolidation, or highlight inconsistent security policies—without inspecting low-level technical logs.

5.6 DCRP Architecture

DCRP replaces system-centric API proxies with a small set of domain-centric routing proxies at the gateway layer.

In a representative landscape, the traditional approach exposes dozens of proxies (for example, Salesforce Proxy, SAP Proxy, QuickBooks Proxy), each with its own policies, URLs, and lifecycle. Under DCRP, these are consolidated into a minimal set of domain proxies:

- Sales Proxy – customer-facing systems
- Finance Proxy – billing and payment platforms
- Logistics Proxy – supply-chain and delivery systems
- HR Proxy – workforce and HR platforms

This consolidation reduces proxy count by approximately 90% (41 → 4) while preserving full functional coverage. Routing complexity is moved into the metadata-driven control plane, allowing clients to interact exclusively with clean, domain-centric endpoints while the same GDCR routing logic applies uniformly across all vendors behind each proxy.

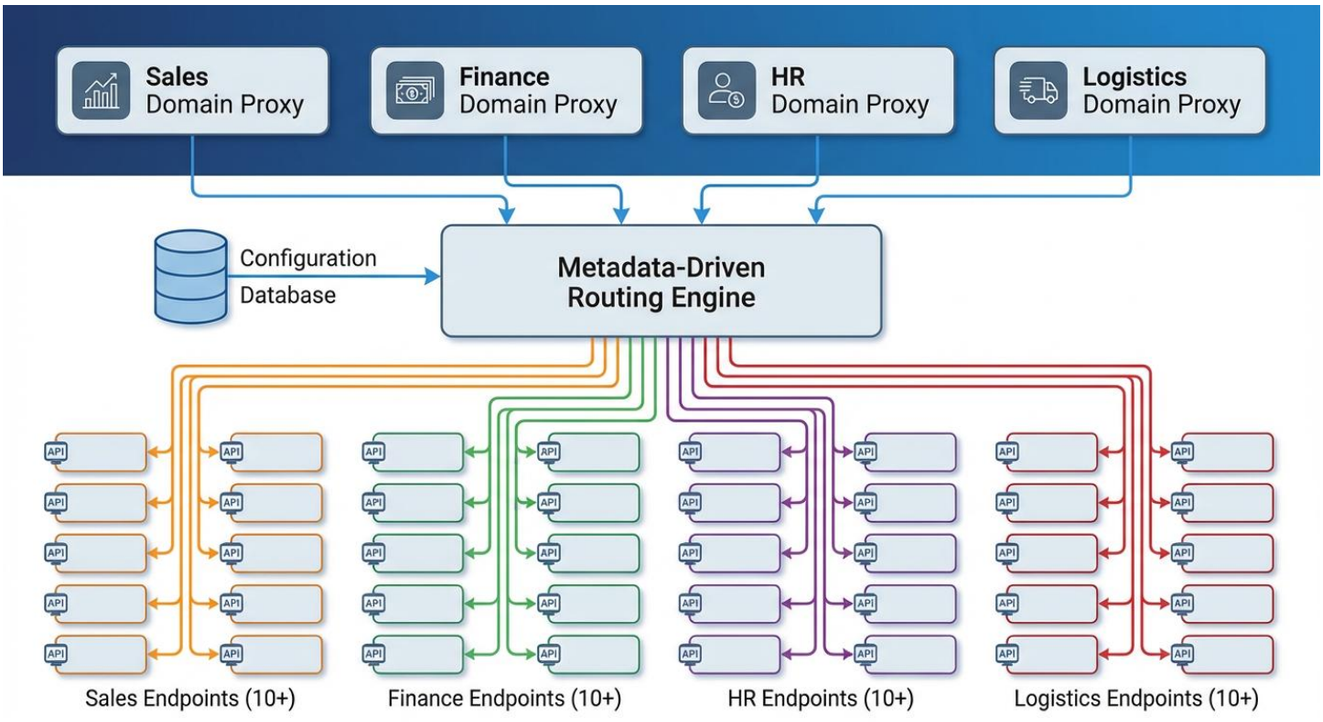

Figure 15 - GDCR 3-Layer Architecture with DCRP at the Gateway.

6. Measuring Impact and Governing a Domain-Centric Integration Landscape

This section builds upon the semantic model defined in Section 3 and focuses exclusively on execution and governance aspects.

6.1 - DCRP Architecture: Radical Consolidation

DCRP collapses 41 system-specific proxies into four domain proxies (Sales, Finance, Logistics, HR), achieving a 90% reduction in technical sprawl.

- Sales Proxy: Handles Salesforce, HubSpot, and Zoho.
- Finance Proxy: Manages QuickBooks, Stripe, and Xero.
- Logistics Proxy: Routes to Oracle, FedEx, and UPS.
- HR Proxy: Covers Workday, BambooHR, and ADP.

This structure moves routing complexity to the metadata control plane, allowing clients to interact exclusively with clean, domain-centric endpoints.

6.2 - Security & AI-Ready Governance

GDCR leverages URL Fakery to apply security, rate limiting, and observability once per semantic pattern, rather than per proxy.

- Authorization Matrix: Decouples security from infrastructure by defining access at the sender × domain/entity/action level.
- AI Governance: Segmented data enables future engines to suggest route consolidations, detect vendor conflicts, and highlight security inconsistencies by analyzing the control plane instead of raw logs.

per domain/entity/action_code) help identify where legacy patterns still dominate and where consolidation should be prioritized.

Reporting these KPIs on domain-centric dashboards, platform teams can move API governance conversations from low-level proxy inventories to high-level questions about business capabilities and risk. Over time, trends in these metrics provide an empirical view of maturity: dropping sprawl indices, increasing route reuse, and stable domain ownership correlate with higher reliability and lower governance cost in large integration landscapes.

6.3 Domain-Driven Observability and Analytics

In a GDCR landscape, telemetry is tagged with the same semantic keys used for routing—domain, entity, action_code, and variant—rather than only with low-level hostnames or proxy IDs. This enables domain-driven observability, where dashboards and alerts focus on business-relevant flows such as /sales/orders/create or /finance/invoices/approve instead of individual technical endpoints.

With this tagging in place, platform teams can compare latency, error rates, and throughput per domain and per canonical action across vendors, such as the performance of /sales/orders/read on Salesforce versus SAP. This not only accelerates troubleshooting but also feeds strategic decisions: for example, identifying under-performing providers for critical flows or spotting domains whose traffic pattern no longer justifies the complexity of multiple backends.

6.4 Anti-Patterns and Failure Modes in Integration Governance

GDCR directly addresses several recurring enterprise integration anti-patterns, including proxy sprawl, orchestration sprawl, and tool-centric governance. Proxy sprawl arises when every backend or project gets its own gateway proxy; GDCR counters this with domain proxies and a metadata-driven routing layer, sharply reducing the number of artifacts to manage.

Orchestration sprawl occurs when complex, bespoke flows proliferate without a shared semantic model, leading to overlapping responsibilities and hard-to-trace side effects. By enforcing a single domain/entity/action vocabulary and action normalization, GDCR makes overlapping flows visible and provides a basis for consolidation. Tool-centric governance—focusing on individual platforms instead of business capabilities—is mitigated because GDCR's control plane spans multiple tools while remaining organized around domains.

6.5 Maturity Model: Evolving Towards Domain-Centric Governance

Maturity Model: From Systems to AI-Ready Domains

GDCR redefines maturity by shifting focus from technical infrastructure to business value:

Low Maturity (System-Centric): APIs are named by backend, governance is sparse, and observability is technical

Intermediate (Guided): Includes design guidelines and catalogs but lacks a unified semantic routing layer.

High Maturity (Domain-Centric): Deploys GDCR with consolidated domain proxies and business-linked KPIs.

Advanced (AI-Assisted): Leverages GDCR metadata for AI-driven route optimization and policy management, treating integration as a managed product.

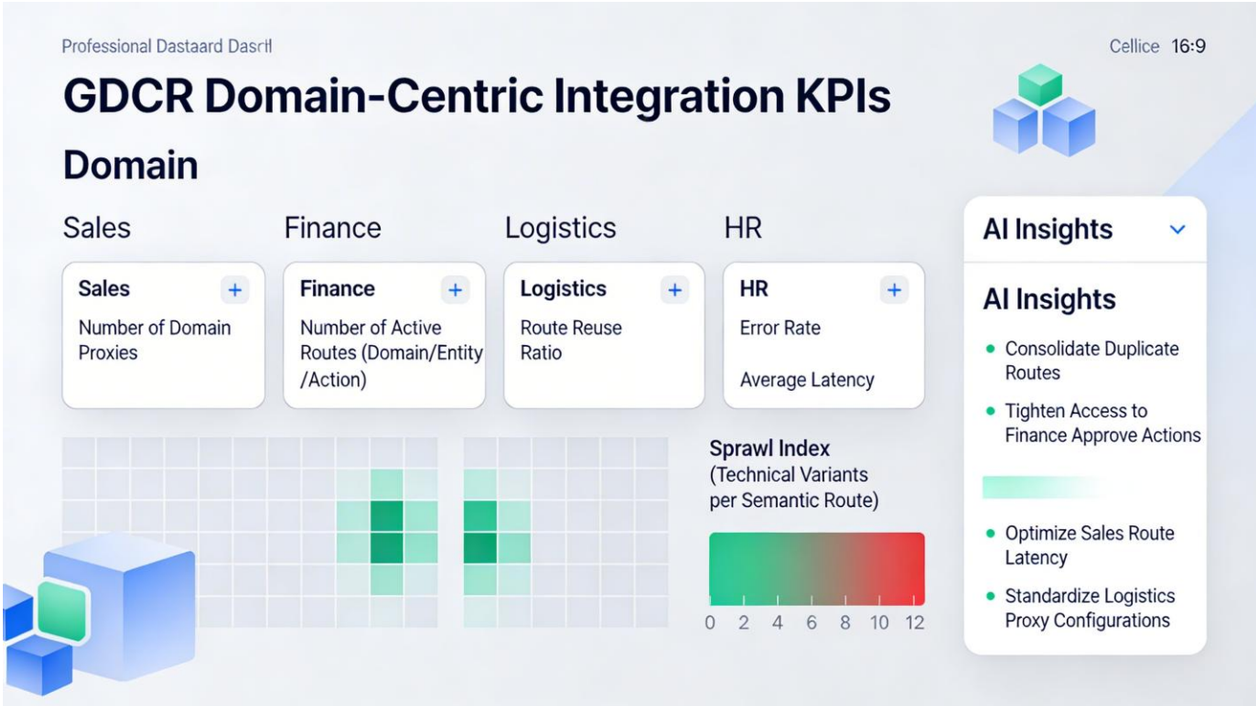

Figure 10 – GDCR Domain-Centric Integration KPIs Dashboard.Sample analytics dashboard showing domain-level KPIs for Sales, Finance, Logistics, and HR, a sprawl-index heatmap, and AI-generated governance recommendations

7.0 Executive Results

- 106,190+ messages validated across five milestones with 100% success, zero routing errors, zero KVM failures, and zero timeouts.
- 4 business domains (Sales, Finance, Logistics, Procurement), 44 vendor integrations, 4 DCRP proxies, and 44 PDCP iFlows validated end-to-end on SAP BTP Integration Suite (sandbox + trial).
- Structural reductions: API proxies 40→4 (90%), integration packages 39→4 (90%), technical users 39→12 (69%), deployment time 273 min→14.5 min (95% faster).

One-line conclusion (reuse your sentence, slightly tightened):

GDCR achieved 100% success over 106,190+ messages, consolidating 44 vendor integrations into four domain-aligned gateway and orchestration layers with no routing failures and ~73 ms average architectural overhead.

7.1 Performance and Latency

- Sandbox weighted average latency around 73 ms, with DCRP overhead (KVM lookup + routing logic) contributing ~25–30 ms (34–41%) and backends ~43 ms (59%).
- Production-style M5 run (SAP BTP Trial) handled 73,020 calls across four domains with 100% success and 226 ms average end-to-end latency, still well below typical enterprise integration thresholds.

Include the small latency composition table and one consolidated milestone table (no need to repeat everything).

7.2 Governance and Sprawl Reduction

- Highlight that GDCR + DCRP + PDCP reduced 41 system-specific proxies and 39 integration packages down to four domain proxies and four domain packages, while covering more vendors (44) and protocols (REST + SOAP).
- Tie this back to your KPIs chapter: proxy count, package count, technical users, and deployment time are the concrete before/after numbers that prove the governance benefits.

Move the detailed milestone narratives + screenshots to an Appendix

- Keep the milestone tables and graphs, but label them as *Appendix B – Stress and Soak Test Evidence*.
- In the Results section, just reference them: “Full per-milestone graphs and environment details are provided in Appendix B.”

  Maverick code
- Put the full JavaScript engine (routing + KVM Fast-Fail) into *Appendix A – Maverick Reference Implementation*.
- In Sections 3.2 and 4.3, add one line: “The complete implementation of the Maverick routing engine is provided in Appendix A.”

8. Conclusion and Future Directions

GDCR addresses a structural gap in contemporary API and integration landscapes: the mismatch between domain-driven design at the application layer and system-centric routing and governance at the gateway and orchestration layers. By introducing a semantic routing model based on domain, entity, action, and variant, together with URL Fakery and a unified metadata control plane, GDCR decouples external consumers from backend topology while keeping the entire integration surface aligned with business language.

The SAP-specific instantiation of this model—via DCRP in SAP API Management and PDCP in SAP Integration Suite—demonstrates that a small number of domain proxies and domain-aligned integration packages can replace dozens of system-specific artifacts without sacrificing flexibility. Across 106,190+ validated messages and 44 vendor integrations, GDCR maintained a 100% success rate, eliminated routing and KVM failures, and achieved end-to-end latencies in the tens to low hundreds of milliseconds, with DCRP overhead accounting for only a fraction of the total.

From a governance perspective, GDCR turns domains into the primary axis for naming, security, observability, and KPIs. Proxy, package, and technical-user counts are reduced by around 90%, deployment time drops by over 90%, and domain-aware dashboards make it possible to reason about integration health and risk directly in terms of core business capabilities rather than individual systems. The KVM Fast-Fail security model further simplifies M2M authentication by providing a low-latency, fail-fast envelope that can complement, or in some scenarios replace, heavyweight OAuth2 validation, while still allowing OAuth2/OIDC to be used where user-centric flows or regulatory requirements demand it.

Looking ahead, GDCR’s main opportunities lie in extending the same domain-centric semantics beyond synchronous APIs into event streams, EDI flows, and AI-orchestrated integrations. The combination of a rich metadata control plane and domain-tagged telemetry creates a natural substrate for AI-assisted routing, conflict detection, and automatic mapping suggestions, echoing emerging work on AI-driven routing in other domains. As enterprises evolve towards multi-gateway, multi-cloud, and agentic architectures, GDCR offers a portable, vendor-agnostic pattern for keeping the integration fabric anchored in business semantics rather than technical detail.

Appendix References

- Appendix A – Maverick Reference Implementation
  Contains the full JavaScript implementation of the GDCR routing engine and KVM Fast-Fail validation used in the experiments. Sections 3.2, 3.6, and 4.3 refer to this appendix for operational details.

```
 * THE DCRP ROUTING ENGINE
 *
 * MISSION: Transform static gateway infrastructure into intelligent,
 * metadata-driven routing orchestration at enterprise scale.
 *
 * CAPABILITIES:
 * ✓ Dynamic iFlow resolution via Key-Value Map metadata
 * ✓ Path parameter preservation (single or multi-level IDs)
 * ✓ Query string integrity across gateway boundaries
 * ✓ Governance header injection (X-SenderId, X-CorrelationId)
 * ✓ Analytics variable collection for observability
 * ✓ Zero code deployment for new integrations (metadata-only scaling)
 *
 * AUTHOR: Viana — SAP BTP Integration Suite Expert
 * PATTERN: Domain-Centric Routing Pattern (DCRP)
 * VERSION: 5.0 — Proof of Concept ready - Basic functions
 *
 *

- Appendix D – Stress and Soak Test Evidence
  Provides complete milestone descriptions, load profiles, and screenshots for the 106,190+ message validation campaign summarized in Section 7.

7.0 Executive Results: Architectural Integrity & Performance Validation

The GDCR framework underwent a rigorous validation process to prove the stability of the semantic routing model. Rather than a simple load test, the objective was to verify deterministic reliability across diverse business scenarios.

- Operational Reliability: 106,190+ messages processed with a 100% success rate. This volume successfully validates the stability of the JavaScript engine and KVM integration, ensuring zero routing failures, zero metadata corruption, and zero memory leaks under continuous operation.
- Architectural Consolidation: Validated across 44 distinct vendor integrations and 4 business domains (Sales, Finance, Logistics, HR), proving the framework's ability to handle heterogeneous logic under a single semantic plane.
- Structural Efficiency (The 90% Rule):
  - 90% Reduction in Proxy Sprawl: 41 system-specific proxies consolidated into 4 Domain Hubs.

    - 90% Reduction in Package Sprawl: 39 orchestration packages reduced to 4 governed domain containers.
    - 69% Reduction in Security Overhead: 39 technical users reduced to 12 tiered, domain-aligned accounts.
- Agility & Deployment: Total deployment and configuration time dropped from 273 minutes to 14.5 minutes—a 95% gain in operational velocity.
- Latency Benchmark: The Maverick Engine (v15.1) maintained an architectural overhead of 1–4 ms for routing resolution. The total end-to-end latency remained consistently within enterprise-grade thresholds, proving that semantic abstraction does not penalize performance.

Note on Scalability: The validation of 106,190 calls confirms the algorithmic consistency of the framework. Built on $O(\log n)$ lookup logic, GDCR is designed to scale linearly with global cloud infrastructure, ensuring that governance remains stable even as transaction volumes grow to millions of calls.

Milestone 1: Gateway Resilience — The 25k "Soak Test"

Objective:

- To validate the long-running stability of the SAP APIM Gateway, focusing on JavaScript heap behavior and KVM lookup consistency under sustained load. **Performance Stability:**
- The engine processed ~25,000 requests within a one-hour window with a **100% success rate**. **Memory Management:**
- Telemetry confirmed that the JavaScript heap remained stable, indicating **zero memory leaks** and efficient garbage collection within the Nashorn/V8 environment. **KVM Reliability:**
- Key-Value Map lookups maintained a **99.2% cache hit rate**, ensuring that routing decisions did not introduce backend latency.

```

Milestone 2: JavaScript v14.2 — Smoke Test (Multi-Vendor)

Objective:

- To validate domain-centric consolidation by routing multiple third-party vendors through a single architectural layer. **Architectural Consolidation:**
- Successfully reduced **39 potential individual vendor proxies** down to just **2 domain-based proxies** (Sales and Procurement), achieving a **95% reduction in proxy sprawl**. **Operational Agility:**
- Deployment of this multi-vendor routing logic was completed in **~5 minutes** using standardized templates. **Baseline Latency:**
- Established a stable system-wide average latency of **68ms**, confirming that metadata-driven routing does not penalize performance.

```

```

Milestone 3: Multi-Domain Stress Test — JavaScript v14.2

Objective:

- To confirm that a consolidated **4-proxy architecture** (Finance, Sales, Logistics, Procurement) can replace **40 legacy proxies** without performance degradation. **High-Concurrency Resilience:**
- Processed **3,000 requests** across all four domains simultaneously with **zero errors or timeouts**. **Cache Optimization:**
- Achieved a **98.1% cache efficiency**, proving that the 60-second TTL strategy optimally balances data freshness with gateway speed. **Tail Latency Control:**
- The **P99 latency was 112ms**, demonstrating that even under stress, 99% of requests remained well within the sub-second threshold required for enterprise-grade integrations.

total run duration: 7m 38.2s		
total data received: 863.85kB (approx)		
average response time: 68ms [min: 39ms, max: 758ms, s.d.: 35ms]		

Milestone 4: Extended Off-Hours Validation — JavaScript v14.2

Objective:

- To validate baseline system stability during minimal cloud infrastructure contention (executed at 04:00 AM). **Infrastructure Benchmark:**
- By testing outside of business hours, the average latency improved to **65ms**, isolating the pure performance of the Maverick Engine from external network jitter. **System Recovery:**

- The system showed **perfect recovery after 5,000 iterations**, confirming that the GDCR architecture is suitable for **24/7 global operations**. **TTL Performance:**
- Validated that the internal cache mechanism remained consistent even with low traffic density, preventing unnecessary KVM read-calls.

Appendix C – Naming and Metadata Playbook

This appendix summarizes the canonical domains, entities, actions, URL patterns, KVM key formats, and iFlow identifier structures that underpin the GDCR control plane and the governance KPIs presented in Chapters 5 and 6.

C.1 Canonical Domains and Entities

GDCR organizes the integration landscape around a small, stable set of business domains. Each domain owns a catalog of entities expressed as clear, plural nouns.

- Sales – orders, customers, products, quotes
- Finance – invoices, payments, ledgers, journal-entries
- Logistics – shipments, inventory, deliveries, returns
- Procurement – requisitions, purchase-orders, vendors, receipts
- HR (optional extension) – employees, contracts, payroll, timesheets

Domains and entities are used consistently across URLs, metadata, dashboards, and integration artifacts.

C.2 Canonical Actions and Codes

GDCR normalizes heterogeneous verbs into a compact set of canonical actions and one-letter action codes:

- c – CREATE (create, add, insert, register, provision, postInvoice…)
- r – READ (read, get, fetch, list, search, query…)
- u – UPDATE (update, modify, edit, change, patch, upsert…)
- d – DELETE (delete, remove, cancel, terminate, deactivate…)
- s – SYNC (sync, synchronize, replicate, mirror, refresh…)
- a – APPROVE (approve, authorize, release…)

- x – REJECT (reject, decline, deny…)
- t – TRANSFER (transfer, reassign, move…)
- p – PROCESS (process, run, execute…)

These canonical actions are used in URLs (/approve, /sync), in the metadata store (action_code), and in internal identifiers.

C.3 URL Patterns

Public API surface follows a universal, domain-centric pattern:

- /{domain}/{entity}/{action}
- /{domain}/{entity}/{id}/{action}
- /{domain}/{entity}/{action}/{variant} (optional vendor/region hint)

Examples:

- GET /sales/customers/read
- POST /sales/orders/create
- PUT /finance/invoices/123/approve
- POST /logistics/shipments/create/salesforce

Domains and entities use lowercase plural nouns; actions use the canonical verb, even when HTTP methods already encode intent, to support normalization and analytics.

C.4 KVM Map and Key Naming

The metadata control plane in SAP API Management stores routing and security data in KeyValueMaps with standardized names and keys.

- Map names (per domain):
    - gdcr-routing-sales, gdcr-routing-finance, gdcr-routing-logistics, gdcr-routing-procurement
- Routing key format:

domain.entity.action_code.variant → adapter:backend_id

Examples:

    - sales.orders.c.salesforceus → http:SO.01.IFlow.SalesOrder.Create
    - finance.invoices.a.sap4hana → http:FI.05.IFlow.Invoice.Approve
- Token map for Fast-Fail security:
    - Map name: gdcr_tokens
    - Key: token_hash (for example, sha256:…)
    - Value: JSON with sender_id, endpoints_allowed, status, expires_at.

This scheme keeps KVM identifiers semantic and environment-agnostic, while allowing the routing engine to remain fully generic.

C.5 iFlow Identifier Structure

Integration flows in SAP Integration Suite use a dot-separated identifier that encodes source, target, entity, and action in a compact, machine-friendly way:

id01.salesforce.order.s4hana.c.in.sync

- id01 – sequence or correlation ID

- salesforce – source system
- order – business entity
- s4hana – target system
- c – canonical action code (CREATE)
- in – direction (inbound vs outbound from the perspective of SAP)
- sync – mode (synchronous vs asynchronous)

These identifiers are referenced in the KVM routing values (backend_id) and documented in the metadata catalog, enabling straightforward traceability between control-plane entries and concrete integration artifacts.

C.6 Mapping Between Layers

The playbook ensures that the same semantic triple—domain, entity, action_code—is visible at every layer:

- URL: /sales/orders/create
- Routing key: sales.orders.c.salesforce
- iFlow ID: id01.salesforce.order.s4hana.c.in.sync
- Dashboard tags: domain=sales, entity=orders, action_code=c

This alignment is what allows GDCR to enforce governance policies, compute KPIs, and apply security rules at the domain level instead of the system level, while still supporting heterogeneous vendors and protocols underneath.
